ABSTRACT

Context. Near-infrared (hereafter NIR) data may provide complementary information to the traditional optical population synthesis analysis of unresolved stellar populations because the spectral energy distribution of the galaxies in the 1-2.5 μm range is dominated by different types of stars than at optical wavelengths. Furthermore, NIR data are subjected to less absorption and hence could constrain the stellar populations in dust-obscured galaxies.

Aims. We want to develop observational constraints on the stellar populations of unresolved stellar systems in the NIR.

Methods. To achieve this goal we need a benchmark sample of NIR spectra of "simple" early-type galaxies, to be used for testing and calibrating the outputs of population synthesis models. We obtained low-resolution (R~1000) long-slit spectra between 1.5 and 2.4 μm for 14 nearby early-type galaxies using SofI at the ESO 3.5-m New Technology Telescope and higher resolution (R~3000) long-slit spectra, centered at the MgI at ~1.51 μm for a heterogeneous sample of 5 nearby galaxies observed with ISAAC at Antu, one of the 8.2-m ESO Very Large Telescope.

Results. We defined spectral indices for CO, NaI, CaI and MgI features and measured the strengths of these features in the sample galaxies. We defined a new global NIR metallicity index, suitable for abundance measurements in low-resolution spectra. Finally, we present an average NIR spectrum of an early-type galaxy, built from a homogenized subset of our sample.

Conclusions. The NIR spectra of the sample galaxies show great similarity and the strength of some features does correlate with the iron abundance [Fe/H] and optical metal features of the galaxies. The data suggest that the NIR metal features, in combination with a hydrogen absorption feature may be able to break the age-metallicity degeneracy just like the Mg and Fe features in the optical wavelength range.

Key words. Infrared: galaxies — Galaxies: abundances — Galaxies: elliptical and lenticular, cD — Galaxies: spiral — Galaxies: stellar content

1. Introduction

State-of-the-art space-based instrumentation can only resolve galaxies from the Local Group well and in the more distant objects we usually can see only the tip of the red giant branch stars which is rarely sufficient for population analysis. This leaves us with the difficult task of trying to recover the stellar population of unresolved galaxies from their integrated properties. The complex mix of stellar populations found in most of them usually makes it possible to constrain only the most recent generation of stars. However, such properties as the stellar kinematics and the present-day metal content are dominated by the overall star formation history, and together with the well known age-metallicity degeneracy (Faber 1973; O'Connell 1986; Worthey 1994) they

often lead to non-unique solutions for the stellar populations. In this respect, the Lick/IDS system of indices pioneered by Burstein et al. (1984) and Faber et al. (1985), and developed further by Trager et al. (1998, 2000, 2005), has been particularly successful for interpreting the integrated optical light of galaxies.

However, new constraints are necessary to interpret more complicated systems and one possibility is to widen the spectral range towards the near-infrared (NIR) because the light in different wavebands is dominated by different populations of stars. The NIR passbands are dominated by light from older and redder star and therefore offer us the possibility to study other stellar populations than is possible with optical spectra alone. In addition, abundance determinations through optical spectroscopy are not possible for heavily reddened evolved stellar populations such as dusty spheroids or some bulge globular clusters hidden by dust (e.g., Stephens & Frogel 2004). NIR spectroscopic observations could overcome these problem because the extinction in the *K*-band is only one-tenth of that in the *V*-band.

Most of the previous work at NIR was focused on either active galactic nuclei (AGNs) or objects with very strong

star formation, including recent surveys of ultra-luminous infrared galaxies (Goldader et al. 1995; Murphy et al. 1999, 2001; Burston et al. 2001), luminous infrared galaxies (Goldader et al. 1997; Reunanen et al. 2007), starbursts (Engelbracht 1997; Coziol et al. 2001), Seyfert galaxies (Ivanov et al. 2000; Sosa-Brito et al. 2001; Reunanen et al. 2002; Boisson et al. 2002), LINERs (Larkin et al. 1998; Alonso-Herrero et al. 2000; Sosa-Brito et al. 2001), and interacting galaxies (Vanzi & Rieke 1997; Vanzi et al. 1998).

Relatively few NIR spectroscopic observations exist for "normal" galaxies. Only Mannucci et al. (2001) provided low-resolution ($R \sim 400$) template spectra for galaxies of different Hubble types, including some giant ellipticals. Such data, together with the corresponding analysis is a necessary first step towards developing a system of spectral diagnostics in the NIR because well-understood galaxies with relatively simple star forming history will allow us to tune the NIR population synthesis models. Recently, Silva et al. (2008, hereafter S08) studied the stellar populations of eleven early-type galaxies in the nearby Fornax cluster by means of K-band spectroscopy.

A few prominent NIR features were first studied by Origlia et al. (1993) who demonstrated that they represent a superb set of indicators for constraining the average spectral type and luminosity class of cool evolved stars. This conclusion was later confirmed by Förster Schreiber (2000) and Ivanov et al. (2004). Furthermore, the same NIR features appear to be promising abundance indicators (Frogel et al. 2001; Stephens & Frogel 2004).

Here we describe two new data sets of high quality NIR spectra of ellipticals/spirals designed to provide a benchmark for future NIR studies of unresolved galaxies: *(i)* low-resolution spectra covering the range from 1.5 to 2.4 μm that include strong features such as CO, NaI and CaI that are traditionally studied, and *(ii)* moderate resolution spectra around the MgI absorption feature at 1.51 μm. This is the second strongest Mg feature in the H- and K-band atmospheric windows (after the feature at 1.71 μm) and at zero redshift it is located in a region of poor atmospheric transmission, making it difficult to observe in stars. However, the redshift of external galaxies moves it into a more transparent region (Ivanov 2001), just the opposite of the 1.71 μm MgI which becomes affected by the red edge of the H-band atmospheric window.

We are only few years from the launch of the James Webb Space Telescope (Gardner et al. 2006), a space-based infrared telescope that will have unprecedented capabilities. Therefore, in the near future the application of NIR spectroscopy to the study of galaxy properties will be limited not by lack of data but by our understanding of spectral features at these wavelengths. Improving the characterization of the NIR indices is a timely step in this direction.

The paper is organized as follows. The sample selection is discussed in Sect. 2. The NIR spectroscopic observations and data reduction are described in Sect. 3. The definition of the new NIR spectral indices and their measurements are given in Sect. 4. Results are discussed in Sect. 5 and summarized in Sect. 6.

2. The sample

Our main sample consists of 14 nearby bright ($B_T \leq 14.1$ mag) and undisturbed spheroids. It was selected to cover a wide range in luminosity and velocity dispersion and to have available Lick/IDS line-strength indices, from the literature. Six of our galaxies are giant ellipticals (NGC 4472, NGC 4621, NGC 4649, NGC 4697, NGC 6909, IC 4296), five are intermediate-size ellipticals (NGC 4478, NGC 4564, NGC 4742, NGC 5077, NGC 5576), one is a bright dwarf elliptical (NGC 3641), and two are bulges of disk galaxies (NGC 4281, NGC 4594; our spectra are dominated by their spheroids). The Mg$_2$ index spans the range between 0.21 and 0.34 mag (Bender et al. 1993), in agreement with other Mg$_2$ literature values, and the central velocity dispersions are between about 130 and 370 km s^{-1}. The galaxy properties are summarized in Table 1.

Four galaxies in the sample exhibit evidence for weak nuclear activity: NGC 4594 and NGC 5077 were identified as LINERs by Heckman (1980); NGC 4472 is a weak Seyfert 2 (Ho et al. 1997) and IC 4296 shows radio and X-ray emission (Rinn et al. 2005). Finally, NGC 4649 is a close companion of the giant spiral NGC 4647 and it may have undergone some tidal stripping (Das & Jog 1999).

The low resolution used for the observation of our sample is not sufficient for characterizing the 1.51 μm MgI feature, so we selected from the ESO Science Archive higher resolution spectra covering the region around the 1.51 μm for a heterogeneous set of galaxies. Although these observations were obtained for other purposes, they provide us with a first glimpse into the behavior of this feature. The properties of these galaxies are also described in Table 1.

3. Observation and data reduction

3.1. SofI low-resolution spectra

Long-slit ($0\!.\!''6 \times 290''$) NIR spectroscopy of 14 galaxies was performed with the SofI (Son of ISAAC) infrared spectrometer (Moorwood et al. 1998b) at the Nasmyth A focus of the ESO 3.5-m New Technology Telescope (NTT) at the European Southern Observatory (ESO) in la Silla (Chile). The detector is 1024×1024 pixels Hawaii HgCdTe array with 18.5-μm pixel size. It is read out in four quadrants and the average quantum efficiency is $\sim 65\,\%$. We used the low resolution grism ($R \sim 1000$) providing spectral dispersion of 10.22 Å pixel^{-1} and a coverage between 1.53 μm and 2.52 μm.

The smaller galaxies were observed in nodding mode, placing them at two different positions along the slit, separated by 150″. In the case of bigger galaxies, the telescope pointing was alternated between the galaxy and a nearby clear sky region to obtain a good sky sampling. We randomly dithered the telescope within a 10″ box along the slit around each position. This dithering, also known as jitter (see e.g. SofI handbook or Devillard 1999), helps us to remove bad pixels, to improve the pixel sampling, and the flat-field correction because on each image the object is placed on slightly different position on the array.

Immediately before or after each galaxy spectrum we observed a B star to measure the atmospheric transmission and the instrument response, always in nodding mode and with a similar airmass to that of the corresponding galaxy. Finally, to calibrate the spatial distortions we also obtained a sequence of stellar spectra placed on 19 equidistant positions along the slit.

The details about the spectroscopic observations are given in Table 2.

The spectra were reduced with the Image Reduction and Analysis Facility (IRAF)[1]. The sky emission was removed either by subtracting the corresponding image in each nodding pair or by subtracting from each object image the average of the preceding and the succeeding sky images, respectively for the two modes of observation described above. The data were flat-fielded with screen flat spectra. Geometric distortion correction was applied along both the spatial and dispersion axes by using an arc frame and the grid of stellar spectra mentioned above, respectively. Simultaneously, the frames were wavelength calibrated. We applied the dispersion corrections, and removed the hot pixels and cosmic ray hits with the algorithm described in Pych (2004). Then, we aligned the individual 2-dimensional spectra along the spatial direction (*i.e.*, along the slit), to combine them together and to extract a 1-dimensional spectrum of the galaxy with apertures as listed in Table 2.

Finally, we removed the telluric absorption. To do this we first created a sensitivity function by multiplying the observed spectrum of the standard by the intrinsic spectrum of a star with the corresponding (or the closest available) spectral type from Pickles (1998). Some residual emissions were observed, indicating that the spectral types of the standards may not be accurate. We fitted these artificial features with a Gaussian, with the IRAF task SPLOT and subtracted them from the sensitivity function. This prompted us to omit the bluest part of the spectra ($\lambda \leq 1.65\,\mu$m) from further analysis because the standards are rich of Hydrogen lines that modify the appearance of the galaxy spectra. Next, we divided the galaxy spectra by

---

[1] Image Reduction and Analysis Facility is a general purpose software system for the reduction and analysis of astronomical data, IRAF is written and supported by the IRAF programming group at the National Optical Astronomy Observatories (NOAO).

this sensitivity function to restore the overall continuum shape of the galaxy spectrum. This process, broken into steps, is illustrated in Fig. 1 and more detailed descriptions can be found in Hanson et al. (1996) and Maiolino et al. (1996). The final reduced spectra were taken to zero redshift (the values used are listed in Table 1) and are shown in Figs. 2 and 3.

3.2. ISAAC high-resolution spectra

Five spectra of galaxies were obtained with ISAAC – a NIR imaging spectrometer (Moorwood et al. 1998a) at Nasmyth B focus of Antu, one of the 8.2-m ESO VLT unit telescopes of ESO Very Large Telescope at Paranal (Chile). It is equipped with a 1024×1024 Hawaii Rockwell HgCdTe array with a spatial scale of 0.146 ″pixel^{-1}. The long-slit ($0\!.\!''3 \times 120''$) medium (R~3000) resolution spectroscopy mode was used. The wavelength coverage spans the range from ~1.48 μm to ~1.62 μm and the central wavelength was chosen according to the object redshift. A summary of the observations is given in Table 2.

Similar to the SofI observations, telescope pointings ware alternated between the galaxy and a nearby empty sky region, or if the dimension of the galaxy were small enough, then by nodding among two positions along the slit separated by about 20″. No jittering was used. Standards were observed in nodding mode soon before or after the galaxy, at a similar airmass. A sequence of stellar spectra placed at equidistant positions along the slit was obtained to calibrate the spacial distortions, as in the case of the SofI data.

The reduction steps were carried out using IRAF and they are the same as for the main data set, albeit with some complica-
Fig. 1. The telluric absorption correction: the wavelength calibrated 1-dimensional galaxy spectrum (a) is divided by the wavelength calibrated 1-dimensional observed spectrum of the standard star (b) and the result is multiplied by the reference of the same spectral type of the standard star (c) from the library of Pickles (1998). The product (d) is the corrected galaxy spectrum. Note the large scatter at ~18000–19000 μm region where the Earth's atmosphere is practically opaque to the radiation.

tion due to the lower signal to noise and longer exposure times. First, the individual images were cleaned from cosmic rays using SPEC_COSM, a cosmic ray rejection script for long slit spectra developed by van Dokkum (2001). Second, bad pixels were masked out before the combination because the small number of images limited the ability of the rejection algorithms to remove the bad pixels during the combination of the individual images. Finally, the highly variable sky background led to residuals in the sky-subtracted images which were removed with the IRAF task BACKGROUND before the geometric distortion correction and the wavelength calibration.

4. Definition of the NIR spectral indices

The NIR spectral indices are usually defined with a central bandpass covering the spectral feature of interest, and two other bandpasses at the red and blue sides which are used to trace a local continuum level through a linear fit to the mean values in both bands, as in Ali et al. (1995), Frogel et al. (2001) and Ivanov et al. (2004). When this is not possible, for example because the feature is at the end of the atmospheric window, then either one continuum band or a fit to the overall shape of the continuum is used, as in Kleinmann & Hall (1986).

Most of the earlier definitions are aimed at stars, where the spectral features are typically only a few km s^{-1} wide, however in galaxies the intrinsic velocity dispersion broadens them to a few hundred km s^{-1}. This forced us to define new spectral indices with broader passbands (Table 3, Fig. 2 and 3). The continuum passbands were placed on regions clear of absorption features, and not (or only weakly) affected by the telluric absorption. Furthermore, we tried to have as wide continuum passbands as possible, to increase the signal-to-noise of the measurements. The passband of each spectral feature was defined to encompass the maximum extent of the feature itself and to avoid, if possible, contamination by other features. For instance, the passband

Fig. 2. *H*-band spectra of the sample galaxies, continuum-divided (i.e., all continua were normalized to 1) and shifted vertically for displaying purposes by adding increasing shifts of 0.25. The position of the main spectral features is shown with dotted lines. The passbands of the MgI (1.71 μm) feature and its adjacent continuum regions are marked with inclined solid and dotted lines, respectively.

of our CO (2.30 μm) index is wide but still only includes the ^{12}CO feature and there is no contribution from the ^{13}CO band head.

We measured the equivalent width (EW) of the lines with respect to a local continuum obtained by fitting a straight line to the "clear" parts of the spectrum:

$$EW = (1 - F_{\text{feature}}/F_{\text{cont}}) * \Delta\lambda \qquad (1)$$

where F_{feature} is the flux inside the feature window, F_{cont} is the value of the local continuum linearly interpolated (or extrapolated, if necessary) at the center of the line and $\Delta\lambda$ is the width of the feature bandpass. The fluxes F_{feature} and F_{cont} are normalized by the bandpass widths. The measurements were performed following the above recipe with a self-written IDL script. The error-bar are derived in the same script by means of Monte Carlo simulations on the measured spectrum considering as noise the RMS of the normalized flux in the continuum region. The average signal-to-noise calculated on the continuum passbands regions is written in Table 2. The corresponding values of each
Fig. 3. *K*-band spectra of the sample galaxies, continuum-divided (i.e., all continua were normalized to 1) and shifted vertically for displaying purposes by adding increasing shifts of 0.25. The position of the main spectral features is shown with dotted lines. The passbands of the NaI (2.21 μm), CaI (2.26 μm), and CO (2.30 μm) features and their adjacent continuum regions are marked with inclined solid and dotted lines, respectively.

Table 3. NIR Spectral indices.

The central wavelength λ_c and bandwidth $\Delta\lambda$ are given for the central feature (Line) and the continuum bandpass at shorter (Cont. 1) and longer (Cont. 2) wavelengths.

Feature	Line		Cont. 1		Cont. 2	
	λ_c (Å)	$\Delta\lambda$ (Å)	λ_c (Å)	$\Delta\lambda$ (Å)	λ_c (Å)	$\Delta\lambda$ (Å)
MgI (1.50 μm)	15040	80	14960	80	15120	80
MgI (1.71 μm)	17098	90	17033	46	17206	100
NaI (2.21 μm)	22070	140	21965	62	22170	40
CaI (2.26 μm)	22647	106	22553	74	22802	172
CO (2.30 μm)	22990	160	22802	172	–	–

NGC 6909	3.60 ± 0.48	2.59 ± 0.46	2.72 ± 0.77	15.22 ± 0.94

equivalent width with their relative errors for all galaxies in the sample are given in Table 4.

Our definitions have intentionally wide bandpasses to make them intrinsically insensitive to the varying velocity broadening of spectral features in the galaxy spectra. To verify this, we measured the indices for broadened spectra of M and K type giants. We choose stars in this spectral range because they are the most representative of the early-type integrated galaxy spectra. (These spectra are a reasonable match to the observed galaxy spectra.) We computed for them the correction factor $C(\sigma)$ for various line-of-sight velocity distribution, as in S08:

$$C(\sigma) = \frac{\text{EW}(\sigma = 0)}{\text{EW}(\sigma)} \qquad (2)$$

the EW of the feature is measured from the stars convolved with a Gaussian with σ given in brackets. We broadened the stellar spectra to velocity dispersion up to 400 km s^{-1} in steps of 50 km s^{-1} and used templates for different spectral stars and from different sources. The corrections for the different spectral indices are shown in Fig. 4. Some of them show a significant scatter,

depending on the adopted stellar spectrum. However, the mean correction are typically small (i.e., $\lesssim$ 15% in the worst case).

5. Discussion and Conclusions

5.1. General appearance of the spectra

The spectra of our sample galaxies appear qualitatively similar in most of the NIR features except for a large spread in the NaI values is present. This similarity is not surprising because we selected mostly giant ellipticals and spheroids, which are all relatively metal rich, have no significant recent star formation, and only weak nuclear activity, if any. This conclusion agrees with Mannucci et al. (2001) who demonstrated that galaxies within the same Hubble type have nearly identical NIR spectra. On the other hand, the large spread of NaI, with respect to the observational errors, appears to be real, and suggests variety of star formation and enrichment histories among the galaxies in our sample. Two of the three galaxies with systematically weaker NaI exhibit strong Hβ, indicating that the weak NaI might be related to the presence of younger stellar populations (the third galaxy lacks optical spectroscopy). The strongest features are the CO absorption bands in both the *H* and *K*-band atmospheric windows. They originate in K and M stars, as can be seen from the libraries of stellar spectra described in Lancon & Rocca-Volmerange (1992), Origlia et al. (1993), Dallier et al. (1996), Meyer et al. (1998),
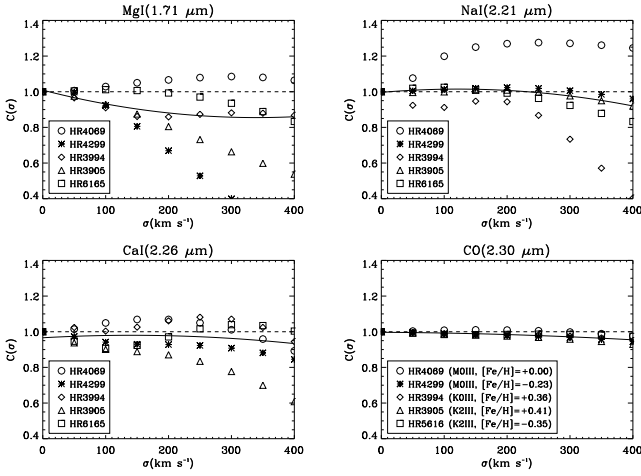

Fig. 4. Correction factors of the NIR spectral index for different values of velocity dispersion. They have been derived by comparing the EW measured in the spectra of the labeled stars before and after broadening them to a particular velocity dispersion. The spectral types of the stars are in a range between KIII and MIII with a spread of [Fe/H] between -0.35 and +0.41. In each panel the solid line is the 2nd order polynomial fitting the data.

Fig. 5. The equivalent widths of the NIR spectral indices, iron abundance [Fe/H], and metal abundance [Z/H] in the sample galaxies as a function of the central velocity dispersion. The labels correspond to the row numbers in the Table 1. The open and filled circles refer to quiescent and active galaxies, respectively. The small and large circles refer to galaxies with an age between 5 and 10 Gyr and >10 Gyr, respectively. Galaxies with no known ages were assumed to be old. The dashed lines corresponds to the relations find by S08. The solid line in each panel represents the linear regression (y = ax + b) through all the data points except for #4, #12 and #14. The Pearson correlation coefficient (r) and the results of the linear fit are given. Typical error bars are shown.

Wallace & Hinkle (1997) and Förster Schreiber (2000). A number of weaker metal absorption features are visible as well: SiI at 1.589 μm, MgI at 1.711 μm, NaI at 2.206 and 2.209 μm and CaI at 2.261, 2.263, and 2.266 μm. They are also present mostly in cool stars (i.e. Kleinmann & Hall 1986; Origlia et al. 1993; Wallace & Hinkle 1997; Förster Schreiber 2000; Meyer et al. 1998). As mentioned above, we only consider the redder features with $\lambda \geq 1.65\mu$m.

Not surprisingly, our galaxies show no FeII at 1.644 μm or H_2 lines line emission, usually associated with supernova activity and supernova related shocks, respectively. There is also no Brγ emission.

5.2. Behavior of the NIR spectral indices

Evolutionary synthesis models (i.e. Worthey 1994) are the usual method to interpret the behavior of spectral features in galaxies, but the simple comparison of these features with the galaxy parameters can be informative too. For example, the optical indices, Mg_2, <Fe> and H_β show tight correlation with the central velocity dispersion (e.g. Terlevich et al. 1981; Bernardi et al. 1998; Mehlert et al. 2003; Morelli et al. 2008), suggesting that the chemical and the dynamical evolution of ellipticals are intertwined.

The EW of our NIR spectral indices, the iron abundance and metallicity are plotted versus the central velocity dispersion in Fig. 5. The loci of the S08 data (see their Fig. 13) are shown with dashed lines. Among the galaxies, NGC 5077 (#12) and NGC 6909 (#14) possess very weak NaI, CaI lines, and their relative errors are significant. The correlations between the NIR indices and velocity dispersion for the sample galaxies are plotted in Fig 5; the fit do not consider NGC 4281 (#4), NGC 5077 (#12) and NGC 6909 (#14) because of the reasons explained further on. The correlation with CO shows a similar slope as the one found by S08 but with a different zero-point. The different definition of the index and especially the position of the continuum bandpass can lead to a systematic variation of the EW values.
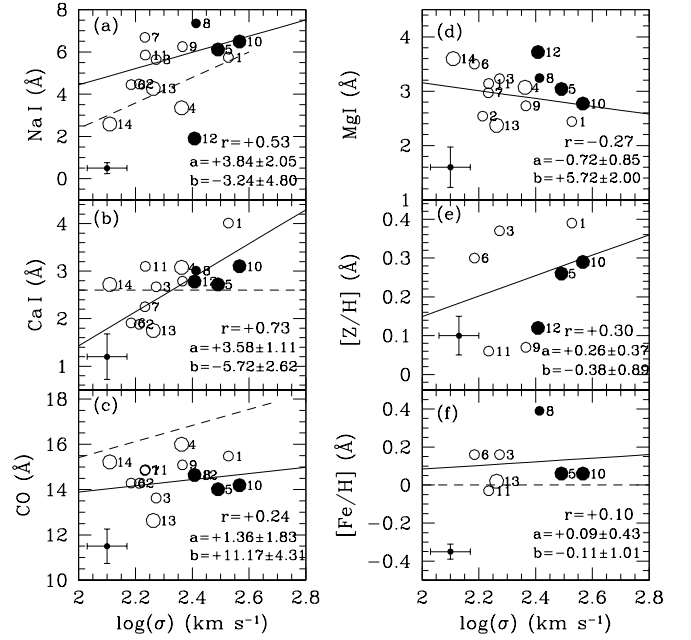

This effect seems to be more evident in the CO band, whose equivalent width is measured with only extrapolated continuum blue-wards of the feature. The agreement with S08 is closer in the NaI versus σ relation although our data show bigger scatter. Without pretending to trace a general conclusion we found relatively large NaI values compared to stars and something similar was also found by S08. The iron abundance [Fe/H] and the total abundance [Z/H] only show very weak correlations. Active galaxies are clustered at the high end of the velocity dispersion distribution which is understandable because their velocity dispersion measurement may be affected by the black hole and the active nucleus. Note that our highest velocity dispersion galaxy is a Type 2 Seyfert and the CO band may suffer some dilution, as discussed in Ivanov et al. (2000).

The EW of our NIR spectral indices are plotted against each other in Fig. 6 and compared to the relations for cluster stars and solar neighborhood giants by S08 and Davidge et al. (2008), respectively. Three galaxies – NGC 4281 (#4), NGC 5077 (#12) and NGC 6909 (#14) – are above the relation of S08 for the cluster stars, which hints at different chemical enrichment history with respect to the rest of the sample. Unfortunately the literature lacks much data about these objects and although NGC 6909 has the lowest velocity dispersion in our sample, these galaxies do not stand out in any respect, including in the optical Mg_2 versus σ diagram. Further investigation of these galaxies is necessary.
Fig. 6. The equivalent widths of the NIR indices plotted against each other. The symbols are the same as in Fig. 5. The dashed lines correspond to the relations found by S08. The dotted line corresponds to the relation by Davidge et al. (2008) for giant stars in the solar neighborhoods. All these relations are plotted in their observed range. The solid line represents the linear regression (y = ax + b) through all the data points except for #4, #12 and #14. The Pearson correlation coefficient (r) and the results of the linear fit are given. Typical error bars are shown.

The rest of our objects populates a locus that follows similar trend as the galaxies of S08. In the CaI versus CO plot we see a correlation with significant scatter, and with a different slope than in S08. Finally, the MgI versus CO plot is dominated by scatter. Galaxies with traces of nuclear activity, evident in other wavelength ranges than the NIR, do not seem to separate from the rest of the sample, and they show no traces of emission lines. Therefore, the contribution of their AGNs is negligible with respect to the rest of the galaxy.

Figure 7 shows the EW of the NIR spectral indices versus the Mg_2 measurements from Bender et al. (1993). NaI, and to a lesser extent CaI and CO, do show trends with respect to Mg_2, with NGC 4281 (#4), NGC 5077 (#12) and NGC 6909 (#14) standing out. The correlation of NaI with both σ and Mg_2 suggests that the NaI feature is dominated by the stellar photosphere rather than by the interstellar medium.

Given that [Fe/H] measurements are not available for the entire sample and that Mg_2 is not representative of the total chemical abundance of a galaxy because of the varying abundance ratios, we attempted to create a combined Iron-and-α-element index similar to that defined by González (1993) and more recently by Thomas et al. (2003):

$$[\text{MgFe}]' = \sqrt{\text{Mg}b \times (0.72 \times \text{Fe}5270 + 0.28 \times \text{Fe}5335)} \quad (3)$$

Such a combined indicator is expected to decrease the effect from the varying α/Fe ratio. Since not all the components of this indicator are available we directly substitute the iron and magnesium indices by defining a new indicator:

$$[\text{MgFe}]'' = \sqrt{Mg_2 \times \text{Fe}5335} \quad (4)$$

Fig. 7. The equivalent widths of the NIR indices plotted against the Mg_2 indices measured by Bender et al. (1993). The symbols are the same as in Fig. 5. The solid line represents the linear regression (y = ax + b) through all the data points except for #4, #12 and #14. The Pearson correlation coefficient (r) and the results of the linear fit are given. Typical error bars are shown.

The results are shown in Fig. 8a-c. The NaI index of NGC 5077 (#12) and the CO index of NGC 6909 (#14) deviate from the main loci of the other galaxies.

To address this issue we plotted the optical indices of these galaxies versus the combined [MgFe]′ index (Fig. 8d). This is an analog of the typical plot (i.e. Worthey 1994) that allows to disentangle the age-metallicity degeneracy: the inverse H_β index is roughly proportional to age while the [MgFe]′ is dominated by metal abundance. The two galaxies exhibit strong H_β which suggests that they are dominated by populations of 3 Gyr or younger (see for example Fig. 1 in S08). NGC 5077 and NGC 6909 are also well separated from the rest of the galaxies on the H_β versus NaI plot (Fig. 8e) which leads us to the conclusion that the NIR indices can be used to create a similar diagnostic plot, but measuring the Brγ feature requires better quality data than the ones described here.

We investigated the behavior of the NIR indices in relation to the H and K-band magnitude and the H-K color but no clear correlations were found.

5.3. Combined NIR metal index

Ground based NIR spectroscopy is much more time consuming than the corresponding optical observations – higher and variable background and detectors with worse cosmetics often require one to sacrifice either resolution or signal-to-noise to obtain the data in a reasonable amount of time. To alleviate this problem, we defined a combined spectral index of all the major K-band metal features:

$$\langle \text{CONaCa} \rangle = (\text{CO} + \text{Na\,I} + \text{Ca\,I})/3.0 \quad (5)$$

Fig. 8. (a-d) The equivalent widths of the NaI, CaI, CO and Hβ indices plotted against the [MgFe]″ index. (e) The equivalent widths of the Hβ index as a function of the NaI index. The symbols are the same as in Fig. 5. The dashed lines correspond to the relations found by S08. The solid line represents the linear regression (y = ax + b) through all the data points except for #4, #12 and #14. The Pearson correlation coefficient (r) and the results of the linear fit are given. Typical error bars are shown.

Fig. 9. The equivalent widths of the newly defined <CONaCa> as a function of the central velocity dispersion (a), Mg₂ (b), Hβ (c), and [FeMg]″ (d) indices. The symbols are the same as in Fig. 5. The solid line represents the linear regression (y = ax + b) through all the data points except for #4, #12 and #14. The Pearson correlation coefficient (r) and the results of the linear fit are given. Typical error bars are shown.

Various weighting schemes were tried to minimize the scatter of the basic relations (Fig. 9). However, the simple average yielded the tightest relations. The carbon and oxygen are α elements, while the sodium and calcium originate in both high and low mass stars. The average value of the CO index for the sample galaxies is ~15 Å, the NaI is ~4.3 Å and the CaI is ~2.7 Å which means that at least 2/3 of the new index is dominated by metals produced mostly in high mass stars, i.e. early in the history of the elliptical galaxies. The other implication is that a relatively limited amount of recent star formation could affect the new index more than it would an iron peak dominated index. The lack of iron peak features in the NIR is well known as it was pointed out in Ivanov (2001).

The new index improves the correlations. For example, the Pearson correlation coefficient is ~10% higher for the ⟨CONaCa⟩ vs. Mg2 and even ~20% higher for the ⟨CONaCa⟩ vs. [MgFe]″, with respect to the respective correlations where only one IR index is used. We derived these relations using only the galaxies with known parameters, i.e. excluding the poorly studied NGC 4281(#4) and, NGC 5077(#12) and NGC 6909(#14) which systematically show peculiarities with respect to the bulk of our sample.

5.4. Average NIR spectrum of the sample galaxies

Studies of composite stellar systems (i.e. galaxies hosting an AGN) often need to subtract the contribution of the underlying galaxy. This prompted us to create an average spectrum of the galaxies in our sample. We used a homogenized subset of eight galaxies, excluding the objects with young populations. We also
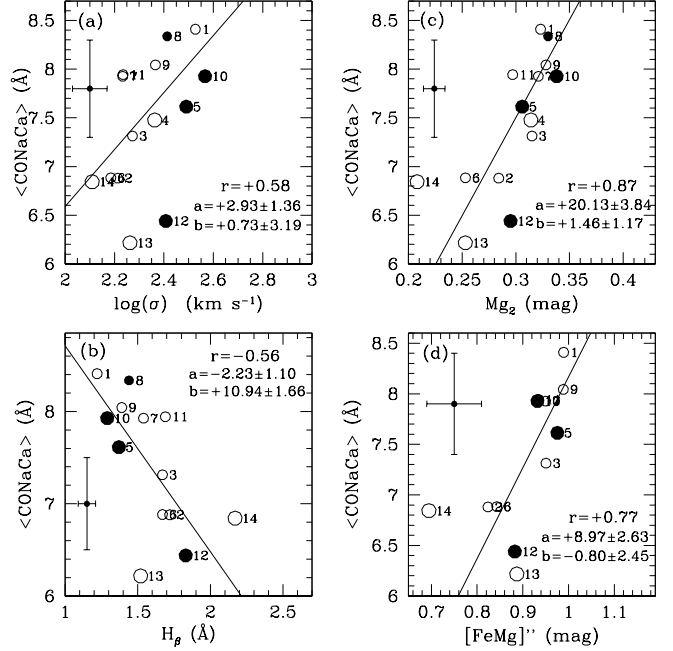

Table 5. Average spectrum of the sample galaxies observed at NTT in arbitrary units and normalized to unity at 22000 Å. The regions with zero r.m.s. at the beginning and the at the and are covered only by one or two spectra. The full table is given only in the electronic version of the journal.

λ (Å)	F_λ	r.m.s.
14944	2.217	0.000
14945	2.384	0.000
14946	2.384	0.000
14947	2.386	0.000
14948	2.130	0.366
14949	2.572	0.254
14950	2.575	0.251
14951	2.578	0.248
14952	2.583	0.245
14953	2.588	0.243
14954	2.595	0.241
14955	2.602	0.240

excluded those with low signal-to-noise ratio. The average age of the galaxies used to create the composite spectrum is 9±2 Gyr (the median is 9.5 Gyr) and the average [Fe/H] is 0.17±0.13 (the median is 0.16). The composite spectrum is shown in Fig. 10 and the values of the spectrum are listed in Table 5, together with the r.m.s. values per Angstrom. We included the H-band section because the artifacts caused by the spectral type mismatch of the standards are minimized by the averaging of galaxies observed at different redshifts.
Fig. 10. Average H- (a) and $K-$band (b) spectrum of sample galaxies normalized to unity at 22000 Å (thick line). The thin lines correspond to the $\pm 1\sigma$ confidence levels. Some of the more prominent spectral features are marked.

5.5. The MgI feature at 1.51 μm

Ivanov et al. (2004) pointed out the possibility of using the MgI feature at 1.51 μm as an α-element abundance indicator in the NIR. With exploratory purposes we obtained spectra of a small and diverse set of galaxies (Table 2 and Fig. 11). To carry out quantitative analysis we defined an index (Table 3) and for the five galaxies we measured equivalent widths of 3.3, 5.0, 3.8, 3.9 and 4.5Å, respectively for Mrk 1055, NGC 1144, NGC 1362, NGC 4472 and NGC 7714. The typical uncertainty is $\sim$ 0.3Å. No corrections for velocity dispersion were applied. Given the diverse nature of the objects, we refrain from drawing any conclusions but we note that the relation between the optical and the NIR Mg features is not straightforward because the only two Mg_2 values that we have from the literature are inversely proportional to our measurements for NGC 1362 and NGC 4472. Nevertheless, these observations prove that it is feasible to measure the NIR MgI feature at 1.51 μm and give a basis for future NIR synthetic spectral modeling.

6. Summary

1. We report on a new data set of NIR spectra of ellipticals/spheroids. The stronger features were measured and show mild correlations with the optical metal features. NIR versus NIR features show a lot of scatter but the diagram of CO versus NaI seems to be a good diagnostic for detecting different chemical enrichment histories.
2. The NIR metal absorptions, in combination with a Hydrogen absorption feature may be able to break the age-metallicity degeneracy, but further investigation and better data are needed to verify this possibility.
3. A new combined NIR index is defined that allows one to interpret lower signal-to-noise data. It is dominated, at about
Fig. 11. Spectra of the galaxies observed with ISAAC in the region of the MgI (1.51 μm). The central wavelengths of the individual MgI lines are shown with vertical solid lines. The passbands for the feature and the adjacent continua are shaded. The spectra were normalized to unity and shifted vertically by 0.5 for display purposes.

2/3 level, by α-elements. We also present an average spectrum of ellipticals/spheroids, built from a homogenized subset of our sample that can be used as template of the integrated early-type galaxy spectra.
4. The strength of MgI feature at 1.5 μm was measured for the first time in a heterogeneous sample of galaxies, providing a new constraint for future NIR spectral synthesis models.
